The Effect Of Curcumin On Hypoxia In Tumor Microenvironment As a Regulatory Factor In Cancer

Keywords
Curcumin, hypoxia-inducible factor (HIF), Von Hippel-Lindau, Cancer, Tumor Hypoxia

Abstract
Hypoxia can lead to different responses from cancer cells, including cell death or survival, partially depending on how long it is exposed. Patients with cancer and under hypoxic tumor conditions have a poorer prognosis and are at greater risk of metastasis. Physiological response to low oxygen levels is controlled by hypoxia-inducible factor (HIF-1). Curcumin, the major component of the rhizomes of Curcuma longa L., reduces HIF-1 levels and function, inhibiting the production of vascular endothelial growth factor (VEGF). In addition, curcumin efficiently inhibits the angiogenesis of vascular endothelial cells triggered by hypoxia. One of the most compelling features that drive continued interest in curcumin is the molecules’ modulation of initiation, promotion, and progression stages of cancer while concomitantly acting as a radiosensitizer and chemosensitizer for tumors. In this review, we discuss the role of curcumin in modulating hypoxia and investigate the mechanisms and regulatory factors of hypoxia in tumor tissues.
The Effect Of Curcumin On Hypoxia In Tumor Microenvironment
As a Regulatory Factor In Cancer

ABSTRACT
Hypoxia can lead to different responses from cancer cells, including cell death or survival, partially depending on how long it is exposed. Patients with cancer and under hypoxic tumor conditions have a poorer prognosis and are at greater risk of metastasis. Physiological response to low oxygen levels is controlled by hypoxia-inducible factor (HIF-1). Curcumin, the major component of the rhizomes of *Curcuma longa* L., reduces HIF-1 levels and function, inhibiting the production of vascular endothelial growth factor (VEGF). In addition, curcumin efficiently inhibits the angiogenesis of vascular endothelial cells triggered by hypoxia. One of the most compelling features that drive continued interest in curcumin is the molecules’ modulation of initiation, promotion, and progression stages of cancer while concomitantly acting as a radiosensitizer and chemosensitizer for tumors. In this review, we discuss the role of curcumin in modulating hypoxia and investigate the mechanisms and regulatory factors of hypoxia in tumor tissues.

**Keywords:** Curcumin, hypoxia-inducible factor (HIF), Von Hippel-Lindau, Cancer, Tumor Hypoxia
Introduction

Cancer incidence and death have not decreased despite significant improvements in cancer therapy over the last three decades (1). For cancer prevention and treatment, it is crucial to understand how genetic changes contribute to cancer's genesis and progression. The development of specific cancer cell targeting methods has reduced tumor growth, progression, and metastatic spread while mitigating some adverse effects (2). Many anti-cancer chemicals with diverse mechanisms of action have been isolated from plant sources (3-6). Curcumin is the major component of the rhizomes of *Curcuma longa* L. (7) and was isolated in pure crystalline form from the turmeric plant in 1870 (8). In the past two decades, curcumin and its derivatives have garnered much attention due to their bio-functional qualities, which include anti-inflammatory, anti-tumor, and antioxidant effects (9-15). These functionalities are linked to the major structural components of curcumin (16). Much research has been conducted on the structure-activity relationship (SAR) to improve curcumin's physiochemical and biological properties.

Hypoxia, or low oxygen levels, is a characteristic of most tumors caused by a disordered vasculature that provides oxygen to the growing tumor. The severity of hypoxia depends on the type of tumor (17). When tumors multiply and expand rapidly, oxygen demand exceeds oxygen supply, and the distance between cells and existing vasculature grows, further hampering oxygen diffusion and creating hypoxia. Hypoxic tissues have poorer oxygenation than normal tissues and are typically between 1% and 2% oxygenated. As evidenced by the high proliferation rate of cancer, a decreased oxygen supply can cause hypoxia due to anemia, a compromised arterial network, or excessive oxygen consumption (18). Cells in this state are permanently unable to function normally because of reduced oxygen pressure. All cells adapt to hypoxia utilizing a homeostatic process. During oxygen deprivation, cells activate genes involved in glucose uptake, transport, metabolism, inflammation, erythropoiesis (EPO), angiogenesis, cell proliferation, pH regulation, and cell death (19, 20).

An important microenvironmental factor in tumors is pathological hypoxia, which facilitates the survival and propagation of cancer cells. Hypoxia can lead to different responses from cancer cells, including cell death or survival, partially depending on how long the cells are exposed. Reactive oxygen species (ROS) are produced due to cycling hypoxia, contributing to tumor cell survival and progression. Hypoxia causes cellular responses that result in blood vessel formation, aggressiveness, metastasis, and resistance to treatment when these subunits are overexpressed. Cancer patients with hypoxia in their tumors have a poorer prognosis and are at greater risk of metastasis. Physiological response to low oxygen levels is controlled by the hypoxia-inducible factor (HIF) (21).

Curcumin reduces HIF-1 protein levels and function, inhibiting the production of vascular endothelial growth factor (VEGF). In addition, curcumin efficiently inhibits the angiogenesis of vascular endothelial cells triggered by hypoxia (22).
Curcumin inhibits HIF-1 activity, resulting in the downregulation of HIF-1-targeted genes. Curcumin can disrupt one of the two HIF-1 subunits, aryl hydrocarbon receptor nuclear translocator (ARNT), in various cancer cell types, which can suppress the HIF-1 expression. However, ARNT expression can reverse curcumin-induced HIF-1 inhibition. According to previous research, curcumin can oxidize and ubiquitinate ARNT, resulting in its degradation by proteasomes. In response to turmeric administration, mice with hepatocellular carcinomas expressing Hep3B exhibited reduced tumor growth and expression of EPO, ARNT, and VEGF. According to these findings, curcumin's anti-cancer properties are related to its ability to inactivate HIF-1 by ARNT degradation (23, 24).

In this review, we discuss the role of curcumin in modulating hypoxia and investigate the mechanisms and regulatory factors of hypoxia in tumor tissues.

**Curcumin**

Curcumin exerts its unique anti-tumor efficacy primarily via pleiotropic functions resulting in apoptosis and decreased tumor cell growth and metastasis (25-32). Curcumin targets multiple cancer cell lines, including cancer of the prostate, neck, brain, head, lung, and breast (33). Due to its low water solubility and low chemical stability, curcumin’s use is limited, however. In contrast, due to its hydrophobicity, in the presence of hydrogen bonds and hydrophobic interactions, curcumin can bind to fatty acid acyl chains within cellular membranes (25, 34). The structure of curcumin has recently undergone numerous structural modifications in an attempt to overcome these limitations and to improve its anti-cancer potential; indeed, these modifications are designed to increase selective toxicity and improve the bioavailability of these modified curcumin agents against cancer cells. Alternatively, curcumin’s physiochemical characteristics and anti-cancer activity may be enhanced by utilizing alternative delivery strategies (33). Curcumin possesses both preventive and therapeutic effects against cancer (35). Traditional medicine has been used for centuries and is now being studied for its potential use in modern cancer treatment. It is a promising natural agent for cancer prevention and treatment. Curcumin exerts significant anti-cancer properties against numerous human cancer cells that can exert its properties on all the significant stages of carcinogenesis, including cell growth, proliferation, angiogenesis, survival, and metastasis via numerous cellular and molecular processes (36, 37).

**HIF-1α molecular structure and regulation**

Hypoxia-inducible factor (HIF) is a protein heterodimer composed of HIF-α and HIF-β subunits (38). The two units are a part of a family of transcription factors called PER-ARNT-single-minded proteins (PAS) that are components of basic helix loop helix (bHLH) proteins (39). The HIF-α protein has three subunits, while the HIF-β protein has just two subunits (40). Both HIF-1α and HIF-1β are constitutively expressed transcription factor family members with bHLH and PER-ARNT-SIM(PAS) domains, whereas HIF-1α is oxygen-sensitive and destroyed by the proteasome pathway (38). The C-terminal activation domain (CAD) regulates most HIF target genes, while the N-terminal transactivation domains of HIF-1α and HIF-2α are crucial for targeting gene
specificity (41, 42). HIF-1α is rapidly inactivated under normoxic conditions. HIF-1 proteins are hydroxylated by a HIF-prolyl hydroxylase (PHD) at the proline residue. The hydroxylated protein binds to the von Hippel-Lindau tumor suppressor protein (VHL). In order for HIF-1α to bind to pVHL as a component of the ECV complex (Elongin/Culin/VHL), HIF-1 must first be acetylated at internal lysine 532 by the acetyltransferase ARD1 (39, 43). Through the 26S proteasome, this interaction quickly leads to poly-ubiquitylation and destruction. Hypoxic tension impairs PHD and prevents HIF-1α from being hydroxylated, which prevents it from binding to pVHL and degradation. Because of this, HIF-1α builds up and moves into the nucleus, where it dimerizes with HIF-1β. The ATPase-directed chaperone, Hsp90, is thought to provide a second mechanism accounting for HIF-1α stability and degradation. HIF-1’s conformation is altered by direct contact with Hsp90, which also causes HIF-1/ARNT heterodimers to form (44). The balance between cellular HIF-1 production and destruction is precise under normal conditions. In addition to HIF-1’s stability in intra-tumor hypoxia, hyper-activation of HIF-1 and reduced degradation can also be seen under normoxic conditions. This probably happens because of several strong growth-stimulating factors (i.e., cytokines and growth factors) or oncogenic signaling factors (i.e., nuclear factor kappa B (NF-κB) and mitogen-activated protein kinase (MAPK)). These factors may stimulate HIF-1, which may cause it to translate and activate downstream pathways that result in cancer (45). Changes in the phosphatidylinositol-3-kinase significantly impact the activation of the HIF-1α protein (PI3K) oncogenic and other oncogenic pathways (46). PI3K cascade alterations usually aid in the growth of cancer through a variety of pathways, consisting of the constitutive activation of receptor tyrosine kinases (RTKs), which activates PI3K, the PTEN (the loss of tumor suppressor phosphatase and tension homologue), PI3K mutations, and AKT improper regulation (47, 48). Numerous target genes whose protein products control important body functions are affected by HIF.

HIF-1α: A Cancer Treatment Target

Angiogenesis

Vascular differentiation is a vital part of the development and pathophysiology of tumors. HIF1 induces the production of stromal cell-derived factor 1 (SDF1), nitric oxide synthase (NOS), adrenomedullin (ADM), VEGF, angiopoietin 2 (ANGPT2), and stem cell factor (SCF) to stimulate the angiogenic response (49). HIF-1 also regulates the activity of the G protein receptor, calcitonin receptor-like receptor (CRLR), which stimulates angiogenesis along with another pro-angiogenic protein, Semaphorin 4D (Sema4D) (50).

Metastasis

HIF-1, which triggers epithelial-mesenchymal transition changes (EMT) and cancer metastasis, directly regulates the transcription factor TWIST (51). In addition, HIF-1 controls the expression
of adhesion molecules, E-cadherins, and matrix metalloproteases that are involved in the cellular processes (52).

**Glucose metabolism**

In cancer cells, anaerobic glycolysis replaces mitochondrial oxidative glycolysis. Glyceraldehyde-3-P-dehydrogenase (GAPDH), lactate dehydrogenase A (LDHA), hexokinases (HK 1 and 2), pyruvate kinase M (PKM), glucose transporters 1 and 3 (GLUT1, GLUT3), and solute carrier family 2 member (SLC2A1) are only a few of the enzymes modulated by HIF-1 (53). It should be noted that HIF-1 also acts on two glycolytic enzymes, namely MCT4 (monocarboxylate transporter), as well as PDK1 (pyruvate dehydrogenase kinase), which causes a change in cancer cells how to expend their energy (54, 55).

**Cell survival and proliferation**

Human embryonic stem (hES) cells' full pluripotency requires hypoxic culture. Several growth factors, including EPO, platelet-derived growth factor (PDGF), insulin-like factor-2 (IGF2), transforming growth factor (TGF), connective tissue growth factor (CTGF), and plasminogen activator inhibitor-1 (PAI-1) are regulated by HIF-1 (55).

**Effect of Curcumin on HIF in Cancer**

The abnormal structural intra-tumoral blood vessels that are functionally present in cancer regions are evidence of hypoxic regions in human cancers due to their rapid cell proliferation. It is noteworthy that intra-tumoral hypoxia increases the risk of invasion, metastasis, treatment failure, and patient death (56). Curcumin suppresses the HIF-1 pathway under hypoxia, which decreases VEGF expression in both tumor and stromal cells and suppresses angiogenesis. The tumor vasculature is aberrant because tumor-activated endothelial cells have unique gene expression profiles and luminal cell-surface receptors. The leaky and constricted blood arteries that characterize this aberrant vascular network also cause more localized hypoxia, producing a vicious cycle. As a result, tumor cells undergo a ROS (superoxide)-generating hypoxia-reoxygenation cycle that, perhaps via enhanced ROS (superoxide anion) generation, is responsible for a more aggressive phenotype (57). Another characteristic of solid tumors is low extracellular pH, and acidosis is caused by hypoxia in the tumor microenvironment (58, 59). A hypoxic environment around tumoral cells facilitates the accumulation of HIF-1α and HIF-2α (60).

Curcumin promotes transcriptional activation of HIF1, which induces the expression of genes related to cellular metabolism and growth, regulation of angiogenesis, cell survival, and death in a hypoxic environment. At the same time, hypoxic signaling is involved in embryonic development and can be exploited in the physiologic modulation of tumor cells (61). Low oxygen levels induce tumor cells to switch from oxidative phosphorylation to glycolysis, leading to the generation of...
metabolic acids in most malignancies (62). These alterations, like enhanced angiogenesis, are mediated by HIF-1α-driven transcription, which upregulates glucose transporters and glycolysis-related genes (63). Li et al. (64) have found a significant correlation between hypoxia, GLUT-1, and the uptake of 18F-fluorodeoxyglucose (18F-FDG) (65). A key signaling pathway that regulates metabolic activities is the mTOR pathway. By controlling important transcription factors like HIF-1α, mTOR affects numerous locations along the glycolytic process (66). HIF-1α's expression is reliant on mTORC1 and mTORC2 (67). Both mTORC1 and mTORC2 are crucial for tumor cells' glucose absorption and glycolytic metabolism (68). Therefore, using mTOR inhibitors to regulate the metabolism of tumors and the malignant microenvironment will become a cutting-edge anti-tumor therapy (69).

Increasing evidence has described a high level of HIF-1α in malignant tumoral cells, whereas normal cells carry low amounts of HIF-1α. Notably, HIF-1 inducible genes and increased levels of HIF-1α are strongly accompanied by the aggressive behavior of tumors and, therefore, poorer prognosis. Thus, HIFs are essential for tumor progression; conversely, their repression has decreased tumoral growth, angiogenesis, and metastasis (70). Recently, HIF-1 inhibiting techniques have emerged as a new therapeutic target in cancer therapy. Additionally, due to its anti-cancer potency through affecting multiple gene transcription and signaling pathways, curcumin, highlighting HIF inactivation in an oxygen-, concentration- and time-dependent manner, has attracted increased attention in oncology. Curcumin treatment led to HIF-1α degradation in primary cultures of human cancer cells but HIF-1α enhancement under normoxic conditions. One of the most compelling abilities that direct continued interest is curcumin's capacity to suppress all cancer initiation, promotion, and progression stages and act as a radiosensitizer and chemosensitizer for tumors (19).

Observations of the present research revealed that the anti-tumor effects of curcumin are not only exerted by modulation by expression of key cell survival regulatory proteins but also via modulation of disparate signaling and regulatory pathways. For example, exposure of tumor-bearing mice cells to curcumin resulted in pro-apoptotic PUMA gene expression and activation of caspase-3, implicating the involvement of curcumin in caspase-dependent apoptosis. Interestingly, HIF-1α has been shown to play a regulatory role in the expression of multidrug resistance-1 (MDR-1) and PUMA. Apoptosis induction and tumor cell survival regulation have been reported as the results of MDR-1 expression. Altered tumoral microenvironment O2 saturation and pH condition might also contribute to the modulation of MDR-1 expression (71, 72).

The poor bioavailability of curcumin in preclinical studies has led to the development of several novel curcumin analogs. Bromophenol curcumin (73) and tetrahydrocurcumin (74) exert antiangiogenic effects in cervical cancer of animal models through the Akt/VEGF signaling pathway and also by reducing HIF-1α at both microvascular concentrations and expression levels. Platinum-based (DDP) drugs are the basis for chemotherapeutic treatment of various human tumors and have significantly improved patient outcomes. In recent years, multidrug resistance by
cancer cells has been a significant therapeutic obstacle, with less than a 15% survival rate at five years. HIF-1α has been identified as a unique mediator of MDR proteins. MDR may be attributed to the fact that amplified HIF-1α levels were found in the DDP-resistant lung cancer cell lines under normoxic conditions (75). In other studies, oxygen deprivation as the key stimulator of HIF-1α overexpression was closely correlated with DDP and doxorubicin resistance in lung cancer (76) and treatment failure in early-stage invasive cervical cancer (77). On the other hand, HIF-1α knockdown by HIF-1α-specific siRNA showed a promising reduction in chemoresistance in the human lung adenocarcinoma A549 cell line (78).

Combination therapy of DDP with curcumin significantly reversed DDP resistance via abrogation of A549/DDP cell proliferation, disruption in HIF-1α amplification, and induced apoptosis through caspase-3 activation and HIF-1α degradation (75). These findings help to reason the curcumin's employment as an anti-tumor agent with therapeutic potential to raise the efficacy of the current regimens in cancer treatment.

**Modulatory pathways**

Although hypoxia is considered a primary inducer of HIF-1 transcription, other stressors can also motivate HIF-1 expression, such as a rise in the HIF-1α level following endoplasmic reticulum stress. The thioredoxin (Trx) system is a key antioxidant system generally overexpressed in hypoxic tumor cells and influences HIF-1α expression (79). So that under hypoxic stress, Trx inhibitors can prevent angiogenesis by suppressing HIF-1. With its potential to target the Trx system, Curcumin is considered an anti-cancer drug via mechanisms of reduction in intracellular-redox potential, the elevation of oxidative stress, and induction of cell death (80).

In many cancers, chemotherapeutic agents reduce primary tumor growth by inhibiting tumor angiogenesis. Anti-VEGF therapy, however, has had a poor response, as intra-tumoral hypoxia associated with impaired angiogenesis is responsible for the formation of HIF-1-dependent metastases and the expansion of cancer stem cells. Experiments have shown that overexpression of HIF-1 in colorectal and pancreatic cancer cells increases vessel density and tumor growth. Notably, some cancer studies have found a positive correlation between overexpression of HIF-1, resistance to radiotherapy, and mortality of the patients (56). Furthermore, curcumin may play pivotal roles in tumor suppression via the downregulation of HIF-1α protein levels and suppression of pro-angiogenic VEGF under hypoxia-induced angiogenesis of the tumor environment.

Curcumin restrains the amplification of VEGF utilizing NF-κB regulation. On the other hand, NF-κB and HIF-1α regulate the expression of one another interdependently. They are known to be involved in similar processes like cell apoptosis. Under severe hypoxia, arising p53 levels promote Mdm2-dependent HIF-1α degradation. The p53 tumor suppressor prevents hypoxia-induced HIF-1α expression by augmenting its proteasomes and ubiquitination (Figure 1) (81).

The balance of TH1/TH2 cytokines is associated with tumor cell apoptosis. Indeed, in tumor-bearing mice, curcumin therapy has decreased the level of TH2 and inhibited the expression of stress-adapting proteins Hsp70 and Hsp90 and anti-apoptotic Bcl2 proteins involved in cell apoptosis.
survival regulation (82). Studies show that T-regulatory (Treg), tumor-associated macrophages (TAMs), myeloid-derived suppressor cells (MDSCs), and cells are highly infiltrated in intertumoral hypoxic regions (69). During prolonged hypoxia exposure, activated HIF-1α may result in cytotoxic lymphocyte inactivation, such as CD8 T cells and natural killer (NK) cells, impairing their anti-tumor activity (83, 84). Additionally, increased lactate synthesis in tumor microenvironment (TME) can render cytotoxic lymphocytes, including CD8 T and NK cells, diminishing their anti-tumor activity (85). The elevation of HIF-1α-dependent PD-L1 expression in tumor cells, and antigen-presenting cells as dendritic cells and macrophages, which is critical in suppressing anti-tumor immunity by cancer cells, is strongly influenced by hypoxia (86). Hypoxia accelerates B cells' glycolytic rate, inhibiting class switching and decreasing proliferation while increasing death. At crucial points in B cells' development, HIF will become active, which may help determine how they develop and function. Reduced germinal center B cells, impaired affinity maturation, recall response, and early memory B cell development are all effects of constitutive HIF stabilization caused by Vhl deletion. Therefore, the overactivation of HIF caused by hypoxia diminishes B cell function (87, 88). Thus, it suggests another mechanism of the decline in tumor cell survival following curcumin administration associated with HIF-1α, in accord with the observation that upstream modulation in the expression of HIF-1α is attributed to the regulation of Hsp70, Hsp90, and Bcl2 (89, 90).

Several studies have demonstrated the anti-cancer effect of curcumin, focusing on targeting subunits of HIF-1 and HIF-2α. Ströfer et al. explored curcumin’s inhibitory effect with higher concentrations, and its result revealed lower HIF-1 subunits and HIF-2α protein levels in MCF-7 breast cells, Hep3B, and HepG2 liver cells (81). While another study showed that curcumin negatively regulates stable HIF-1 protein levels under hypoxia, it did not affect the mRNA level of HIF-1 in HepG2 cells (74). In another study, Sarighieh et al. investigated curcumin’s ability to control HIFs expression under both hypoxic and normoxic conditions in MCF-7 cells and cancer stem-like cells (CS-LCs), in which curcumin treatment resulted in decreasing the level of HIF2α protein expression but did not affect HIF-1α expression. Moreover, it was hypothesized that curcumin treatment in CS-LCs could inactivate HIF-1 through degrading ARNT and help inhibit tumor metastasis other than the direct inhibitory effect on its transcription (91). Another study also demonstrated that of the two subunits of HIF-1, curcumin only destabilized ARNT in several cancer cell types, and also ARNT expression helps curcumin inhibit HIF-1. This study's results suggested that curcumin's anti-tumor activity is due to the inactivation of HIF-1 through the degradation of the ARNT (23).

Tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein gamma polypeptide (YWHAG) is a prognostic factor in cervical cancer of HeLa and C33A cells involved in cervical cancer. A positive correlation between YWHAG and HIF-1α expression has been detected in cervical cancer cells, as YWHAG expression promotes further HIF-1α overexpression. This interaction affects the proliferative and invasive capacity of cervical cancer cells. On the hand, YWHAG knockdown leads to a reduction of the pentose phosphorylation pathway-related
proteins, matrix metalloproteinase (MMP) 2 and MMP9 expression, and glucose uptake. Combining cisplatin with curcumin promotes cell apoptosis through the YWHAG pathway and its interaction with HIF-1α, affecting the pentose phosphorylation pathway (92).

**Different cancers**

The remarkable preventive and therapeutic effects of curcumin can be exerted through various signaling pathways, as mentioned above. Therefore, here we provide up-to-date evidence and findings of clinical studies on curcumin contributions and its effect on tumor cells' survival and death by focusing on its anti-cancer effects via HIF signaling pathway regulation.

**In vitro studies**

While curcumin has shown benefits in different models of cancers by applying a wide variety of cellular properties, including anti-inflammatory activity by suppression of NF-kB induced by TNF-a or inflammatory cytokines such as IL-6 and IL-8 in response to acid exposure, antioxidant property by activating PPAR-γ; anti-bacterial and antiproliferative activities, recent interests have focused on its use in cancer treatment via HIF regulation (93) (Table 1).

In non-small cell lung cancer, curcumin has been shown to promote apoptosis by inducing anti-apoptotic protein Bcl-2 degradation (94). In a recent study, suppression of the pan-caspase inhibitor, zVAD-fmk resulted from combined curcumin and DDP treatment suggests that curcumin via a caspase-3-dependent mechanism can sensitize DDP cytotoxicity through triggering A549/DDP apoptosis. HIF-1α overexpression was detected in DDP-resistant cells under normoxic conditions (75). Likewise, as an adjuvant chemotherapeutic agent in lung cancer treatment, curcumin has played a major role in conquering MDR and improving treatment efficiency by promoting A549 and A549/DDP cell apoptosis via a miRNA mechanism. Cisplatin resistance, the most common chemotherapeutic agent used in NSCLC, is reversed by curcumin (95).

Numerous *in vitro* and *in vivo* studies exhibited curcumin's capability to abrogate the proliferation of pancreatic cancer cells through inhibition of COX-2, CD-31, VEGF, IL-8 and suppression of TGF-β via NF-κB and HIF-1α downregulation (96). Another study showed that a new synthetic curcumin analog (difluorinated-curcumin) could inhibit miR-21, miR-210, HIF-1α, and cancer stem cell (CSC) signature gene markers in human pancreatic cancer cells *in vitro* under hypoxic conditions (97). In another study, curcumin, in a dose-dependent manner, either as a single agent or in combination with 5-fluorouracil (5-FU), has resulted in chemoresistance reduction of gastric cancer cells via phosphorylation of STAT3 (98), the exact anti-cancer mechanism of curcumin has been observed in squamous carcinoma cells (99). In colon cancer cells, curcumin has been reported to induce apoptosis and restrain the growth of cancer cells through repression of specificity protein (Sp) transcription factors Sp1,3,4 and Sp-regulated genes, suppression of genes like NF-κB (p65 and p50), BCL-2, cyclin D1, and hepatocyte growth factor receptor (c-MET) (100). As in PC3...
prostate cancer cells, curcumin suppressed fibroblasts-induced invasion and epithelial to mesenchymal transition via MAOA/mTORC1/HIF-1α signaling pathways repression (101).

The reported data of in vitro and in vivo on hepatocellular carcinoma (HCC) that accumulation of hypoxia-mediated HIF-1α has led to stimulation of β-catenin expression increase in EMT process, enhancement in invasive and metastatic behavior is suggestive of curcumin chemotherapeutic efficiency in HCC (102). PD-L1 protein expression, an enhancer of T-cell activation, which can be a direct target of HIF-1α blockade under hypoxia, is upregulated when STAT3 and HIF-1α get jointly overexpressed. Accordingly, Zuo et al. proved that crosstalk between HIF-1α and STAT3 signaling pathways was the mechanism of curcumin action in significant downregulation of PD-L1 expression when applied as a co-treatment in hepatic cancer (103).

Synthesized formulations called ceria nanoparticles, coated with dextran and loaded with curcumin, represent promising small molecule drug therapy for neuroblastoma cells while producing only minor toxicity in healthy cells. It induced stabilizing HIF-1α, prolonged oxidative stress, and induced caspase-dependent apoptosis with a specifically more pronounced effect in MYCN-amplified cells (104). It also has been reported that curcumin shows potent antiproliferative and apoptotic features in hemangioma endothelial cells via recruiting the HIF-1α-VEGF axis and its contribution in suppression of MCL-1 as a key downstream effector of HIF-1α pathway (105).

According to the literature supporting curcumin’s capability in the regulation of miRNA expression, curcumin affects nuclear traffic by inhibiting specific importins related to HIF-1α nuclear translocation like IPO7 together with CRM1 (exportin1 or Xpo1), which was found down-regulated in curcumin-treated K562 cells in CML treatment. Interestingly, it was demonstrated that curcumin could significantly inhibit HIF-1α activity without affecting its expression and employing a new molecular scenario which was up-regulation of miR-22 expression level (106).

Curcumin pretreatment has shown protective effects against severe relocated conditions, so-called hypoxia, and reoxygenation (H/R) triggered injury after BMSCs-based cell therapy. Curcumin pretreatment remarkably led to H/R-induced mitochondrial dysfunction by expediting the production of adenosine triphosphate and suppressing ROS accumulation. Furthermore, it has notably induced Epac1 and Akt activation while Erk1/2 and p38 deactivation and HIF-1α destabilization in BMSCs (107).

A study also showed that expression of HIF-1α was significantly upregulated in oral squamous cell carcinoma (OSCC) associated with areca quid chewing, and arecoline-induced HIF-1α expression was down-regulated by NAC, curcumin, PD98059, and staurosporine (108).

Another study showed that in addition to Let-7C aerobic glycolysis inhibition by targeting HIF-1α, it can regulate cancer progression and metabolism by inhibiting the lin28/PDK1 pathway. Furthermore, let-7C can regulate PDK1 expression through HIF-1α inhibition (109). Obaidi et al.
reported the cancer chemosensitization potential of curcumin through the induction of let-7C on RCC (110).

**In vivo; animal and human studies**

Consistent with the strong *in vitro* studies and the Many molecular efficacies of curcumin involved in the progression and promotion of cancer, demonstrated in cell culture systems, it has provided a passionate basis to progress the studies on curcumin into animal and human subjects.

Curcumin’s efficacy as a chemopreventive agent in GI cancers, including oral (111), esophageal (112), stomach (113), colon (113), liver (114), and also various extra-intestinal malignancies such as head and neck squamous carcinoma (115), lung (116), kidney (117) and hematological cancers (118), in different animal models, mainly rodent, is well established. Treatment with curcumin and its analogs in mice carrying HCT116 and HT-29 cell xenografts have resulted in the reduction of angiogenesis in gastrointestinal cancers, and due to the low bioavailability of orally administered curcumin, gastrointestinal cancers, and especially esophageal cancer seem to be more suitable for curcumin as an anti-cancer regime (119, 120). Similarly, in a mouse model, curcumin application reduced tumorspheres of H460 cells via inhibition of the JAK2/STAT3 signaling pathway (121).

In another study by Zhao et al., the administration of curcumin attenuated the degree of fibrosis and inhibited the proliferation of hepatic stellate cells in the CCl4-induced liver fibrosis in rats (122). Recent evidence indicated the profound effect of HIF-1 on regulating profibrotic mediator production by macrophages and the transcription of central mediators of tissue remodeling, such as TIMP-1, PAI-1, and CTGF pathways. It was concluded that liver fibrosis is promoted by HIF-1α and at least partly through the ERK pathway, an important marker in fibrogenesis (122).

More recently, curcumin has been evaluated in several clinical studies as a potential therapeutic in human cancers. In one study, oral administration of curcumin to 25 patients with oral leukoplakia, gastric metaplasia, bladder cancer, cervical intraepithelial metaplasia, or Bowen’s disease resulted in tumor regression in a proportion of these patients (123). In other uncontrolled studies, topical application of curcumin in 62 patients with oral cancerous lesions led to tumor shrinkage in 10% of the patients and symptom reduction by 70% (124). High-dose oral curcumin administration resulted in disease stability or regression in four out of 21 patients with advanced fatal pancreatic cancer (125). Also, another clinical trial has reported significant clinical outcome improvements in curcumin combined with standard docetaxel chemotherapy regime in patients with advanced and metastatic breast cancer (126). Ultimately, as the promising results and interests in the therapeutic effect of curcumin continue to grow, several other clinical trials are ongoing investigating its chemotherapeutic potential in gut cancers, pancreatic cancer, systemic inflammatory diseases, and also Alzheimer’s disease as well.
Conclusions

Curcumin exhibits pleiotropic properties interacting with molecular targets and intracellular signaling in cancer pathogenesis. However, its anti-tumor efficacy via regulation of hypoxia signaling pathways or inhibition of HIF-target genes has received little attention in this field. Due to curcumin’s non-toxicity and tolerability reported in several trials, it is considered a therapeutic supplement in cancer treatment. However, low solubility and poor bioavailability have limited its efficacy profile and hence demand extensive research to overcome this problem and to bring out novel formulations with maximum efficacy. Curcumin’s inhibitory effect on cancer cell development, invasion, and metastasis via targeting HIF subunits in combination with promising results of in vitro, in vivo, and human trials have provided a passionate basis to develop ongoing and further studies to bring curcumin as a therapeutic agent in the treatment of human cancer.

Figure 1. The effect of curcumin on modulatory pathways of tumor cells

Under hypoxic condition the thioredoxin inhibitors such as curcumin can prevent angiogenesis by suppressing HIF1, which results in the elevation of oxidative stress, and induction of apoptosis. Also curcumin may cause tumor suppression by downregulating the HIF-1α protein levels and suppressing the VEGF, which can prevent angiogenesis.

ARNT: Aryl hydrocarbon receptor nuclear translocator, NF-κB: nuclear factor-kappa B, VEGF: vascular endothelial growth factor, Trx: thioredoxin, HIF-1: Hypoxia inducible factor.
